Optimal Inflation Rate for Nepal

Nepal Rastra Bank
Research Department

Abstract

This paper estimates the optimal inflation rate in Nepal based on the data of the period 1978–2016. The novelty of the analysis is that it probes possible nonlinearity of the hypothesized impact of inflation on economic growth using alternative specifications. The results suggest that there exists a threshold effect of inflation. The Ordinary Least Squares method estimates the turning point of inflation to be 6.25 percent while that of the Hansen (2000) method shows the threshold level to be 6.40 percent. The maximum impact on growth associated with the turning point, and at the mean levels of other explanatory variables is quite high at 4.59 percent. The results suggest that Nepal should adopt an inflation target range around the computed optimal inflation rate to lower the inflation expectation and enhance economic growth.

Keywords: Optimal inflation, threshold inflation, exchange rate overvaluation

JEL Classification: E31, E52, E58, O40

I. INTRODUCTION

The fundamental objective of monetary policy management in Nepal is the attainment of high and sustainable economic growth accompanied with price stability. As stipulated in the amended Nepal Rastra Bank (NRB) Act, 2016, NRB is entrusted with multiple objectives of ensuring price and financial stability and favorable balance of payments for sustainable development of the economy. Accordingly, NRB formulates appropriate monetary, foreign exchange and financial sector policies focusing on maintaining price, financial and external stability. In its annual monetary policy statement, NRB also mentions the target inflation rate for the ensuing fiscal year to anchor the inflation expectations at the targeted level.

High and persistent inflation and low economic growth have been major characteristics of Nepalese economy in recent years. In the last five years, the average inflation rate was 8.8 percent, which was higher than the projected inflation by 1.3 percentage point. Inter-country comparison of inflation in the South Asian Association for Regional Cooperation (SAARC) countries shows that Nepal has the highest rate of inflation except Bhutan and Pakistan coupled with low economic growth. The average annual economic growth rate for last five years was 3.4 percent.

High inflation distorts the optimal allocation of resources and retards growth, weakens the external competitiveness, and lowers the domestic financial savings among others (RBI, 2014). It also exacerbates the inflation expectations and creates inflationary spiral in the economy. Therefore, there is a consensus now that high inflation is bad for the economy and central banks around the world strive to fight against the high inflation and maintain it at low level.

However, question arises as to what is the low or the optimal level of inflation that does not adversely affect economic activities? Is it zero, above zero or somewhat higher? Even though there is a broad consensus among the economists and policymakers on the need to maintain inflation at a low level, they have not typically aimed for zero inflation (Billi & Kahn, 2008).

In this regard, maintaining the optimal inflation rate both for short term and mid-term is of paramount importance as it would support high and sustainable economic growth. The impact of alternative inflation objectives on the economic stability and overall economic well being should be understood clearly setting an appropriate inflation which maximizes welfare of the public (Billi & Kahn, 2008). Moreover, communication and making public aware of such optimal rate of inflation leads the central bank to focus all of its efforts to maintain inflation within this limit and enhance its policy effectiveness.

Nepal maintains a pegged exchange rate regime with India, and around two-thirds of its total trade takes place with India. Thus, Nepal’s inflation is significantly influenced by inflation in India. Several empirical studies have shown that Nepal’s inflation is largely determined by Indian inflation (Nepal Rastra Bank, 2007; Ginting, 2007; International Monetary Fund, 2011). In this context, the sustainability of the peg crucially depends on keeping the inflation rate close to that of India. The adoption of the flexible inflation
targeting by India has also necessitates the adoption of a more proactive policy by the NRB in keeping inflation at a lower rate.

In this regard, very few studies have been carried out in Nepal (Bhatta, 2015; Bhushal & Silpakar, 2011). Both these studies use Khan and Shenhadji (2000) methodology which assumes the threshold level of inflation as exogenous. This study aims to contribute to the estimation of threshold inflation by adopting a more rigorous and alternative estimation techniques, where the threshold level is endogenous. Also, alternative estimation methods are used to assess the robustness of the results. The remainder of the study is organized as follows: the second section reviews the theoretical and empirical literature on the threshold level of inflation and the third section discusses the alternative theoretical models and derives the results with concluding observations.

II. THEORETICAL UNDERPINNINGS AND EMPIRICAL EVIDENCE

This section provides review of theoretical and empirical literature on inflation and growth nexus. First, it discusses several theoretical postulates and major channels through which inflation affects growth. Second, it discusses the empirical literature on the optimal inflation rate focusing on developing countries.

There exists an extensive literature on theoretical and empirical studies regarding inflation and growth nexus. Classical theory views savings as the major ingredient for investment and growth. The classical dichotomy between real and nominal variables means that inflation only affects price level, and only the real factors influence economic growth.

The Keynesians apply Aggregate Demand (AD) and Aggregate Supply (AS) to illustrate output inflation relationship. According to this model, in the short-run, the AS curve is upward sloping which implies that stimulating the demand side of the economy affect both prices and output. Based on this concept, Keynesians advocate a positive relationship between inflation and output (Fabayo & Ajilore, 2006). The initial short-run trade-off between inflation and output results from the time inconsistent problem until it lures the producers into more output. However, in the long-run, the AS curve becomes vertical. The policy implication of vertical AS curve is that demand side policy no longer increase the level of output but only the level of price.

The monetarists argued that inflation persists in the economy when the supply of money exceeds the growth rate of the economy for a prolonged period. They challenged the Philips' argument of inflation and output trade-off and suggest that wages adjust accordingly as the workers anticipate the future rate of interest.

The neo-classical economists developed the portfolio management theory and propounded how individuals manage their wealth substituting current consumption for future consumption. Tobin (1965) suggested that inflation causes individuals to substitute out of money and into interest earning assets, which leads to greater capital intensity and promotes economic growth. It predicts the positive effect of inflation on economic growth.
On the other side, neo-Keynesian economists developed the concept of potential output also known as natural output and argued that inflation is determined by the actual level of output and level of unemployment. If the actual level of output is higher than its potential level and unemployment is below the natural rate, inflation accelerates that causes to shift in Phillips curve to outward indicating higher inflation with higher unemployment (Gordon, 1997).

Endogenous growth theories focus on endogenous factors namely economies of scale, increasing returns or induced technological change for economic growth. According to this theory, rate of return of the capital determines the level of economic growth. Thus, inflation induces substitution of goods to leisure which lowers the return on human capital and thereby reduces the return on all capital and the growth rate (Gillman, Harris, & Matyas, 2001).

Inflation can affect growth through financial intermediaries and transmission channels (Figure 1). First, high inflation can adversely affect the financial market development. Second, financial market development is associated with higher level and efficiency of investment (Li, Min, 2006).

**Figure 1: Transmission mechanism from inflation to economic growth**

Summarizing the theoretical literature, Drukker et al. (2005) provides four major alternative predictions regarding the impact of inflation on output and growth. 1) No effect—there is no effect of inflation on growth as money is super-neutral with money in the utility function with money (Sidrauski, 1967), 2) Positive effect—Money is a substitute for capital, hence inflation has a positive effect on long-term growth (Tobin, 1965), 3) Negative effect—Money is complementary to capital in the cash in advance model causing inflation to have a negative impact on growth (Stockman, 1981), 4) Threshold effect—the effect of inflation on growth depends on the threshold level. Beyond the threshold level, inflation has a negative effect on growth due to its impact on financial market efficiency arising from informational asymmetries and exacerbating financial market frictions (Huybens & Smith, 1998).
III. EMPIRICAL EVIDENCE ON THRESHOLD INFLATION AND ECONOMIC GROWTH

The optimal rate of inflation can be estimated on the basis of the threshold effects in the relationship between inflation and growth. Inflation below the threshold level supports economic growth and inflation above the threshold retards the economic growth. While the theoretical discussions point out the detrimental effects of ‘very’ high inflation, the empirical evidence on the appropriate or the optimal level of inflation is mixed. The empirical literature on the optimal inflation rate can be broadly classified into two groups. One group of literature analyses the cross-country data to estimate the average optimal inflation. The second group focuses on a specific country to derive the threshold rate of inflation. The literature also tends to distinguish between the optimal inflation rate in developing countries and advanced economies. For the advanced economies, there is a consensus that inflation rate between 1 to 3 percent corresponds to price stability while for the emerging and transition economies inflation in the range of 4 to 5 percent would be desirable (Reserve Bank of India, 2014).

Based on these theoretical underpinnings, a large number of empirical studies have been carried out. Several cross country and single country studies have demonstrated both the linear and nonlinear relationship between inflation and economic growth. The non-linear nexus depicts the threshold effects i.e., structural break point of inflation which has important policy implications to the central banks (Fisher, 1993).

A recent report by the RBI summarizes various empirical studies that have attempted to estimate the threshold inflation in India (Reserve Bank of India, 2014). Various studies using different methodologies and time periods suggest the threshold inflation in India ranges between 4 to 7 percent. The latest estimation for the threshold effect in India using the logistic smooth transition (LSTR) model suggests the upper bound for India to be at around 6 percent (Reserve Bank of India, 2014). Based on this seminal study, India adopted flexible inflation targeting, with the objective of gradually reducing inflation and fixing the inflation target of 4 percent with a band of +/- 2 percent.

One of the most often cited and replicated studies by Khan and Senhadji (2001) estimates the threshold inflation using a balanced panel data from 1970 to 2003 for both developing and advanced countries. The authors estimate the threshold inflation for developing countries to be between 10.62 percent and 11.38 percent beyond which inflation significantly slows growth. The threshold inflation for advanced countries is estimated to be much lower between 0.89 percent and 1.11 percent (Khan & Senhadji, 2001).

There are several empirical studies on the threshold inflation for an individual country. These studies employ various time periods and methodology to estimate the threshold inflation. Table 1 provides a summary of literature review on the empirical estimates of inflation.

There are very few empirical studies in Nepalese context to understand the relationship between inflation and output growth. Using the time series data of growth rate of GDP and inflation for the period of 1975 to 2010, the study by Bhusal and Silpakar (2011)
have estimated 6 percent inflation as the threshold inflation level for Nepal. This study includes inflation as a single independent variable in the growth equation. However, the overall model is not robust and it has not examined the significance of the existence of the threshold. Bhatta (2015) estimates the threshold level of inflation employing the methodology of Sarel (1996) and Khan and Senhadji (2001). This study estimates 6 percent inflation as a threshold for Nepal.

IV. EMPIRICAL ESTIMATION OF THRESHOLD INFLATION

This section undertakes the empirical estimation of the threshold inflation in Nepal. First, based on the theoretical underpinnings of the growth model, an empirical model is postulated. Second, the model is estimated using the ordinary least squares (OLS) method and threshold estimation technique recently developed by Hansen (2000).

4.1 Model and Estimation Method

The model specification is based on the augmented Solow-Swan growth model (Mankiw et al. 1992). The model incorporates the human capital, apart from the inputs of labour and physical capital in the neo-classical growth model (Mankiw, Romer, & Weil, 1992; Spolaore & Wacziarg, 2013).

In recent times the empirical literature on growth has moved from the ‘proximate’ determinants to ‘deep’ determinants which impact on the resource endowment and productivity growth (Spolaore & Wacziarg, 2013; Rodrik, 2003). ‘Deep’ determinants of growth focus on various factors such as: (a) geography; (b) trade integration; and (c) institutions (Rodrik, 2003). However, due to unavailability of data on geographic and institutional variables, we confine the analysis to trade integration only.

The next important question is concerning the choice of the other explanatory variables. The empirical studies on the determinants of growth utilize a host of explanatory variables including inflation rate (Barro, 1997; Bosworth & Collins, 2003; Sala-i-Martin, 1997). The choice of the explanatory variables in this study is chosen both based on the empirical growth literature and data availability in Nepal. The reduced form of growth equation to be estimated is as follows:

\[ gdppcg_t = \alpha y_{t-1} + \gamma_1 inf_t + \gamma_2 inf_t^2 + \beta_1 sav_gdp_t + \beta_2 life_t + \beta_3 open_t + \beta_4 over_exch_t + \delta dummy + \epsilon_t \] .......... (1)

where \( gdppcg_t \) = real GDP per capita growth. The explanatory variables are as follows (with the postulated signs of the regression coefficients of the corresponding variables in parentheses):

\[ y_{t-1} \] = lagged real GDP per capita (in log),
\[ inf_t \] = percentage change of Consumer Price Index in Nepal (inflation),
\[ inf_t^2 \] = inflation squared,
\[ sav\text{-}gdp_t \] = savings to GDP (percent),
\[ life_t \] = life expectancy at birth,
\[ open\text{-}gdp_t \] = trade openness (total trade to GDP),
\[ over\text{-}exch_t \] = exchange rate overvaluation,
\[ dummy \] represents the dummy variables to capture the episodes of devaluation (1981, 1986, 1992) of Nepalese rupees and political events (1987, 2009) that contributed to high inflation.

The initial or the lagged level of per capita GDP captures the conditional ‘convergence effect’ or the catch-up effect. The coefficient of initial per capita GDP is expected to be
negative because convergence hypothesis postulates that poorer countries tend to grow faster compared to richer countries. Another explanatory variable, savings-to-GDP ratio is regarded as a crucial determinant of growth. According to the Harrod-Domar growth model increasing the savings rate will increase the growth of output by increasing investment (Harrod, 1939; Domar, 1946). Moreover, savings attract foreign investors by opening opportunities for the domestic investors for equity participation in the joint venture (Aghion et al. 2009). Trade openness, which is also taken as a proxy for trade liberalization, has also been widely used in the empirical literature as one of the determinants of economic growth. Nepal embarked on a journey to liberalize the economy in the late 1980s, with major reforms on trade fronts. Consequently, total trade gradually increased, which potentially has helped to spur productivity growth. Similarly, life expectancy captures the level of human capital.\(^1\)

The degree of exchange rate overvaluation is also included as an explanatory variable in growth model\(^2\). In an influential paper, Rodrik (2008) argues that undervaluation of the currency stimulates economic growth and overvaluation is associated with slow growth. He derives the index of undervaluation by taking the difference between the actual real exchange rate and the Balassa-Samuelson-adjusted rate. Due to large number of out-migrants in Nepal, per capita income can not capture the productivity gain. We therefore, adjust the formula for undervaluation/overvaluation by using net foreign assets as a proxy of productivity of labour force working abroad. The degree of overvaluation/undervaluation is defined as the portion of real effective exchange rate that is not explained by the GDP per capita growth and the growth in the net foreign assets.

\[
growth_{rer_t} = \alpha + \beta\text{GDPPC}_t + \text{NFA}_t + \epsilon_t \quad \text{(2)}
\]

Where, \(growth_{rer_t}\)=growth rate of real effective exchange rate index, \(\text{GDPPC}_t\)=GDP per capita growth, \(\text{NFA}_t\)=growth in net foreign assets. Thus, the degree of over/undervaluation is obtained by the difference between the actual and the predicted values (that is the residuals) of real effective exchange rate. We expect the sign of this variable to be negative.

The model includes the quadratic term for inflation to examine the possible non-linear and threshold effect of inflation on growth. Low level of inflation can be beneficial to growth as it provides an incentive to producers, but once it surpasses a certain threshold it might have negative effect on growth due to uncertainty and distortion of the price signals for efficient allocation of resources.

Then the turning point implied by the inflation-growth relationship is estimated using the formula for the quadratic equation. Specifically, the turning point is estimated by setting the first partial derivative of Equation 1 to zero:

\[1\] The Penn World Table Version 9 estimates the “Human Capital Index”. However, the data are not available for the recent two years.

\[2\] I am thankful to Madhav Dangal for suggestion to include this variable.
\[
\frac{\partial (gdp_{pcg_t})}{\partial (m_{c_t})} = 0, \text{ which implies, } inf^* = -\frac{y_1}{2y_2}
\]

The significance of the turning point is estimated based on the Wald test for confidence interval using the delta method (Cameron & Trivedi, 2009). Due to the presence of squared inflation term, the main effect or the marginal effect of inflation and its significance is also reported in the regression estimations.

The growth rate associated with the estimated inflation turning point is also important as statistical significance of the turning point may not be economically significant. Thus, the maximum growth rate is also estimated at the turning point of inflation and mean values of the other explanatory variables. The significance of the maximum impact is also tested using the delta method.

The ordinary least squares (OLS) method is used to estimate the model. Augmented Dickey Fuller test, Phillips Perron test and Dickey-Fuller Generalized Least Squares (DFGLS) tests are used to test for the unit roots of the variables before estimating the regression. In order to avoid the spurious regressions, appropriate transformation of the variables is performed to make the variables free from unit roots. In order to account for the time series nature of the data, the standard errors are adjusted using the heteroskedasticity and autocorrelation consistent (HAC) Newey-West estimator up to some lag (Newey & West, 1987).³ The rule of thumb to choose the optimal lag is given by \(0.75^*T^{(1/3)}\), where \(T\) denotes the number of observations used in the regression (Stock & Watson, 2011).

In addition to the Ordinary Least Squares (OLS) estimation of model 1, we estimate a modern threshold regression approach based on Hansen (2000). The relationship between inflation and growth within Hansen (2000) framework can be expressed as follows:

\[
y_t = \theta_1 x_t + e_t, \quad q_t \leq \gamma \quad \text{ .......... (3)}
\]

\[
y_t = \theta_2 x_t + e_t, \quad q_t > \gamma \quad \text{ .......... (4)}
\]

Where \(y_t\) denotes the real GDP growth rate at time \(t\), \(x_t\) is the vector of explanatory variables including inflation, and \(e_t\) is the error term. The variable \(q_t\) represents the threshold variable that splits the sample into two regimes depending on the value of \(\gamma\). Equations 3 and 4 can be rewritten as a single equation as follows:

\[
y_t = \theta' x_t + \delta x_t(y) + e_t \quad \text{ .......... (5)}
\]

Where \(\theta = \theta_2, \delta = \theta_2 - \theta_1, \quad x_t(y) = x_t d_t(y)\), and the dummy variable \(d_t(y) = \{q_t \leq \gamma\}\)

³ The formula for the Newey-West correction of standard errors is a bit involved and is not reproduced here.

Hansen (2000) derives the asymptotic distribution of the least squares estimate of $\hat{\gamma}$ of the threshold parameter. Thus, this method is an improvement over the popular Khan and Shenhadji (2001) method as it endogenizes the threshold parameter and provides its statistical significance. Equation 5 can be expressed in matrix form as:

$$Y = X\theta + X_\gamma \delta_n + e \quad \text{........... (6)}$$

Where the regression parameters $(\theta, \delta_n, \gamma)$ are estimated by the OLS or Maximum Likelihood Estimator, when $e_t$ is iid and $N \sim (0, \sigma^2)$. Hansen (2000) shows that the threshold parameter $\hat{\gamma}$ can be obtained by minimizing the concentrated sum of squared error function, $S_n(\gamma)$:

$$S_n = S_n(\hat{\theta}(\gamma), \hat{\delta}(\gamma), \gamma) = YY - Y'X^*_\gamma \left(X^*_\gamma X^*_\gamma\right)^{-1} X^*_\gamma Y \quad \text{........... (7)}$$

The threshold value can now be uniquely defined as:

$$\hat{\gamma} = \text{arg min}_n S_n(\gamma) \quad \text{........... (8)}$$

The significance of the threshold variable can be tested under the null hypothesis $H_0 = \theta_1 - \theta_2$. However, the parameter $\hat{\gamma}$ is not identified under the null, and hence the classical t-test or Wald test is not applicable. Hansen (2000) derives the asymptotic distribution of the likelihood test variable using the bootstrap method:

$$LR = (S_0 - S_1) / \hat{\sigma}^2,$$

Where $S_0$ is the residual sum of squares (RSS) under the null, $S_1$ is the RSS under the alternative hypothesis ($H_1$), and $\hat{\sigma}^2$ is the residual variance under $H_1$.

### 4.2 Data Sources

Data covers the annual data from the fiscal year 1978 to 2016.\(^5\) The choice of the time period is dictated by the data availability from the earliest period. The main data source is the various issues of Economic Survey published by the Ministry of Finance. The data for per capita GDP is taken from the World Development Indicators.

The summary statistics of the data used for estimation is presented in Table 2. The table reports only the summary statistics of 38 observations omitting the ‘outliers’ of inflation greater than 20 percent and negative economic growth.

---

\(^5\) Though the initial data starts from 1976, due to the transformation of variables (that is, taking the lag or growth and differencing resulted in a loss of observations.

Figure 2 depicts real GDP growth and inflation against time. There does not seem to be a discernible relationship between economic growth and inflation. Figure 3 plots economic growth against inflation rate in order to inspect the relationship between these variables. The quadratic trend seems to better fit the data than the linear trend. However, the relationship does not include the effects of other explanatory variables.

V. RESULTS

Before estimating the models we need to ensure that dependent variable (real GDP growth) and explanatory variables are integrated of the same order (Enders, 2004). Augmented Dickey Fuller test, Phillips Perron test and Dickey-Fuller Generalized Least Squares (DFGLS) tests are used to test for the unit roots of the variables. The tests reveal that the inflation variable is stationary while other variables are non-stationary. Since, the dependent variable is stationary, all the non-stationary variables are transformed into growth form to ensure that all variables are stationary. The latter transformation possibly results into the loss of information and renders the interpretation of the regression coefficients of those variables a bit difficult. However, since our main interest is the estimation of quadratic inflation-growth relationship, this transformation is unlikely to affect our results.
The OLS estimations of the model 1 are reported in Table 3. The first column of the Table 3 shows that there is no statistically significant relationship between inflation and growth when we have a basic set of conditioning variables without the squared inflation term (Model 1, Table 3).

However, with the full set of conditioning variables in columns 2–4 (Table 3), the quadratic term of inflation becomes significant at 5 percent level. Moreover, the joint test of significance of both the linear and squared inflation term shows that the combined effect is significant at 5 percent level. The negative coefficient of the squared inflation terms suggests that there is possibly an inverted relationship between inflation and growth.

*** p<0.01, ** p<0.05, * p<0.1

The turning point implied by the inflation-growth relationship on Model 4 (Table 3) is given in Table 4. The turning point of inflation occurs at 6.25 percent which is significant at 1 percent level. However, the standard error is quite large resulting in a wide confidence interval. The growth impact associated with this level of inflation depends on
the value of other covariates. If we fix the values of other covariates at means, the maximum real GDP growth impact associated with the ‘optimum’ level of inflation is 4.59 percent. The confidence interval of the maximum impact is small compared to the threshold inflation.

**Threshold regression**

As an alternative estimation of threshold inflation, Models 3 and 4 are estimated using Hansen (2000) methodology. First, the null hypothesis of no threshold effect is tested using 10,000 bootstrap replications, the p-value for the threshold model using inflation rate is marginally significant at 0.011. The test suggests that there is a sample split based on the threshold level of inflation at 5 percent level of significance.

Figure 4 shows the graph of the normalized likelihood ratio sequence LR\(_n\)(\(\gamma\)) as the function of threshold inflation. The LS estimate of \(\gamma\) is the value that minimizes this graph, which occurs at \(\hat{\gamma} = 6.40\)%. The 95% critical value of 7.35 is also plotted, so we can read off the asymptotic 95% confidence set \(\hat{\Gamma}^*\)=[6.40, 9.30] from the graph where LR\(_n\)(\(\gamma\)) crosses the dotted line. These results suggest that there is an evidence of two-regime specification, though there is considerable uncertainty about the value of the threshold.

The comparison of the threshold estimates from the OLS and the threshold estimations show that there is some evidence of threshold effect of inflation. The confidence intervals also overlap in these cases, showing the robustness of the result. Thus, the
results broadly suggest that the threshold inflation falls within the range of around 6 to 9 percent. The wide confidence intervals of these estimations may also be a result of few observations available for estimation.

The estimations of threshold inflation suggest that there is a sample split of two regimes based on inflation rate. We assume the sample split level of 6.5 percent and re-run the regressions. Table 5 indicates that below the 6.5 percent threshold, inflation has a might have a positive impact on growth. When inflation exceeds 6.5 percent, it seems to have negative impact on growth, though the result is not statistically significant. Due to sample split, the number of observations in both samples was reduced, and the regression coefficients obtained may not be very reliable.

VI. CONCLUSION

From the regression results, there is some evidence to suggest the existence of a threshold level of inflation in Nepal. The OLS method estimates the turning point of inflation to be 6.25 percent while that of the Hansen (2000) method shows the threshold level to be 6.40 percent. However, the confidence intervals of the threshold level are large in both estimations suggesting the uncertainty of the estimates. This optimal range of inflation, however, is consistent with earlier findings in the literature on developing countries (Khan and Shenhadji, 2001). The maximum impact on growth associated with the turning point, and at the mean levels of other explanatory variables is quite high at 4.59 percent.

The large standard errors associated with the threshold estimations may be due to the small sample size, data limitations and short-run developments exerting a significant impact on inflation – such as failure of agricultural crops, high prices of imported products and depreciation in the exchange rate. Several previous studies have also argued that the inflation in Nepal is significantly affected by other non-economic structural and political factors. Moreover, the above threshold estimates are based on past data, and a more forward-looking approach is needed to assess the appropriate level of inflation. The uncertainty in the level of threshold level of inflation also suggests that it is better to adopt a ‘target’ range or band of inflation instead of point estimate in Nepal. A range also enhances transparency and predictability in the monetary policy by signaling the maximum tolerance levels of monetary policy to accommodate unanticipated shocks (RBI, 2014).

Given the pegged exchange rate regime and about two-third of total trade with India, Nepal’s inflation is mostly influenced by India. Thus, the sustainability of the peg crucially depends on maintaining the inflation close to that of India to prevent the misalignment of exchange rate. The average annual inflation differential of Nepal with India since 1976 has been around 1.5 percent. With the adoption of flexible inflation targeting by Reserve Bank of India, inflation has come down significantly in India, and the RBI has committed to target the inflation level to 4 percent with +/- 2 percent band. Thus, Nepal should also adopt an inflation target range around the computed optimal inflation rate to lower the inflation expectation and enhance economic growth.
